

"Il dispatcher è il modulo del kernel che assegna concretamente il controllo della CPU al processo che è stato appena selezionato dallo scheduler. Mentre lo scheduler implementa la politica decidendo 'chi' è il prossimo a dover essere eseguito, il dispatcher è il meccanismo che esegue materialmente il cambio."

"Per dare il controllo al nuovo processo, il dispatcher deve compiere tre operazioni fondamentali:

1. Effettuare il Context Switch: salva lo stato del processo uscente e ripristina quello del processo entrante.
2. Cambiare la modalità di esecuzione: passa dalla modalità kernel (usata per il context switch) alla modalità utente.
3. Eseguire il salto (Jump): aggiorna il Program Counter per riprendere l'esecuzione del programma utente dal punto esatto in cui era stata interrotta."
